The M2 protein of influenza A virus forms a proton-selective channel that is required for viral replication. It is the target of the anti-influenza drugs, amantadine and rimantadine. Widespread drug resistant mutants, however, has greatly compromised the effectiveness of these drugs. Here, we report the solution NMR structure of the highly pathogenic, drug resistant mutant V27A. The structure reveals subtle structural differences from wildtype that maybe linked to drug resistance. The V27A mutation significantly decreases hydrophobic packing between the N-terminal ends of the transmembrane helices, which explains the looser, more dynamic tetrameric assembly. The weakened channel assembly can resist drug binding either by destabilizing the rimantadine-binding pocket at Asp44, in the case of the allosteric inhibition model, or by reducing hydrophobic contacts with amantadine in the pore, in the case of the pore-blocking model. Moreover, the V27A structure shows a substantially increased channel opening at the N-terminal end, which may explain the faster proton conduction observed for this mutant. Furthermore, due to the high quality NMR data recorded for the V27A mutant, we were able to determine the structured region connecting the channel domain to the C-terminal amphipathic helices that was not determined in the wildtype structure. The new structural data show that the amphipathic helices are packed much more closely to the channel domain and provide new insights into the proton transfer pathway.

1. Introduction

Matrix protein 2, M2, forms a highly selective proton channel that is an important constituent of the influenza virus. It equilibrates pH across the viral membrane during viral entry and across the trans-Golgi membrane of infected cells during viral maturation [1–3]. It is necessary for viral replication and therefore remains an attractive target for ongoing studies aiming at developing anti-influenza drugs. In fact, two similar M2 inhibitors, amantadine and rimantadine, had been successfully used for treating flu A infections [4], but emergence of drug resistant strains has severely compromised the effectiveness of these compounds [5]. Single amino acid substitutions at positions 26, 27, 30, 31, and 34 have been reported to confer drug resistance [1,6,7]. Recent studies indicate that the resistance is rising and now exceeds 90%, with S31N being the most frequent substitution [5,8,9]. Another common drug resistant mutant is V27A, which sometimes coexists with the S31N mutation [10,11]. It has been suggested that the mechanism of V27A resistance may be different than that of S31N [12].

Therefore, in order to fully understand the resistance, it is of high importance to obtain structural data on the V27A mutant. Early structural characterization of the M2 transmembrane (TM) peptide by solid-state NMR (ssNMR) converged on a model of the channel domain [13,14]. In this model, the TM peptides form a left-handed four-helix bundle with a well defined hydrophilic pore. The model shows that the two key gating residues, His37 and Trp41, are inside the pore, and that they physically occlude the C-terminal end of the channel. Recently, high resolution structures of the M2 channel have been determined by X-ray crystallography [15] and solution NMR [16]. The crystal structures of the TM peptide M222–46 were determined at pH 5.3 and 7.3 [15]. Unlike the previous models, the crystal structures show a very wide opening at the C-terminal end of the channel, which was interpreted as the open state [15]. The solution NMR structure was determined for a longer construct M218–60 at pH 7.5, which shows tight assembly of the TM helices (residues 24–46) and the amphipathic (AP) helices (residues 52–60) that is consistent with being in the closed state at the experimental pH ~7.5 [16].

The major controversy between the M222–46 crystal structure and the M218–60 solution structure resides in the location of drug binding. In the M222–46 structure, amantadine binds inside of the channel pore, where the hydrophobic adamantyl cage is...
coordinated by serine hydroxyls and the amine group of the drug does not appear to form any short-range, inter-molecular interactions [15]. The crystal structure led to the proposal that the drug directly blocks proton conduction by physically obstructing the pore [15]. In the M2<sub>18–60</sub> structure, rimantadine binds to the external face of the channel, between two adjacent TM helices, where the amine group of rimantadine is within hydrogen bond distance from the carbonyl of Asp44, and the adamantyl cage interacts with the hydrophobic side chains of Leu40, Ile42, and Leu43 [16]. This lipid-facing binding site suggests an allosteric inhibition mechanism, wherein drug binding stabilizes the closed state.

A recent ssNMR study of M2<sub>22–46</sub> in lipid bilayers reported that both drug sites are present, with the pore site having higher affinity for amantadine than the lipid-facing site [17]. This study also suggests that, upon binding to the channel pore, a fraction of the drug tumbles isotropically and does not appear to form any specific interaction with the pore-lining residues [17]. In contrast, another ssNMR study of M2<sub>18–60</sub> also carried out in a lipid bilayers, showed that rimantadine binding exerts a long-range structural effect on the channel that is more consistent with the allosteric inhibition mechanism [18]. It is not clear if the discrepancy between the different studies is due to the highly truncated construct used, experimental artifacts, or other factors.

In this study, we determined the solution NMR structure of the V27A<sub>18–60</sub> drug resistant mutant. The similarities and differences in the structure and dynamic properties between the wildtype (WT), V27A, and S31N variants allowed an analysis of possible modes of drug resistance. Distinct feature of the V27A channel pore also provides an explanation for its faster rate of proton conduction. Furthermore, owing to the higher quality NMR data acquired for the C-terminal region of V27A<sub>18–60</sub> (as compared to that of WT), the mutant structure shows more clearly the structured region that connects the channel domain to the C-terminal AP helices. Using the overall better-defined structure, we propose a proton transfer pathway during M2 proton conduction.

2. Materials and methods

2.1. Protein expression, purification, labeling, and NMR sample preparation

V27A<sub>18–60</sub> (RSNDSSDPLAVASI1GILHILWILDRLFKEFSYRFEEHGLK) was cloned, expressed, and purified as previously described [16]. Briefly, the protein was expressed into inclusion bodies as a fusion to His<sub>9</sub>–trPLM. The M2 peptide was cleaved using cyanogen bromide in 70% formic acid. The digest was dialyzed against water, lyophilized, and loaded onto a C4 column (Grace–Vydac) in 2:1:2 hexafluoroisopropanol:formic acid:water and separated using a gradient of 3:2 isopropanol:acetonitrile. For the NMR study, the lyophilized peptide was then refolded at 250 mM by dissolving in 6 M guanidine and 150 mM DHPC and dialyzing against the final NMR buffer containing 40 mM sodium phosphate and 30 mM glutamate. The sample was concentrated to a final concentration of 0.75 mM (monomer). Rimantadine was added after concentrating.

2.2. Liposomal proton flux assay

Liposome assay for M2 channels was established based on works from the Schroeder, Miller, and Busath labs [25–27] as described earlier [19]. Briefly, in this assay, a proton gradient was used to drive proton conduction. Liposomes were made with identical pH and ion concentrations inside and outside, but highly buffered inside and only weakly buffered outside. Protein-mediated conductance of protons from the external bath into the liposome interior was initiated by adding hydrochloric acid under continuous rapid mixing. Proton flux was monitored as an increase in pH of the external bath.

2.3. NMR spectroscopy

NMR experiments were conducted at 30 °C on spectrometers equipped with cryogenic probes (Bruker, Billerica, MA). Sequence specific assignment of backbone <sup>1</sup>H<sub>n</sub>, <sup>15</sup>N, and <sup>13</sup>C<sub>α</sub> chemical shifts were accomplished using a combination of the available WT<sub>18–60</sub> resonance assignments and a pair of tr-HNCA and tr-HNCOCA experiments [28,29] recorded with a <sup>15</sup>N<sup>-</sup>, <sup>13</sup>C<sup>-</sup>, and 85% <sup>2</sup>H<sup>-</sup> labeled protein. NOEs involving both backbone and side chain protons were assigned using the 3D <sup>13</sup>N-edited and <sup>13</sup>C-edited NOESYs recorded with NOE mixing times of 110 and 150 ms, respectively, on a sample containing <sup>15</sup>N<sup>-</sup>, <sup>13</sup>C-labeled protein, rimantadine, and deuterated 1,2-dihexanoyl-sn-glycero-3-phosphocholine (D22-DHPC) (Avanti Polar Lipids, Inc.).

2.4. Structure determination of the V27A mutant

The V27A<sub>18–60</sub> structure was obtained by refining a homology model derived from the WT<sub>18–60</sub> structure against V27A NMR restraints (including 948 intra- and 60 inter-subunit NOE-derived distance restraints). A simulated annealing protocol was implemented in the program XPLOR-NIH [30], in which the bath is cooled from 1000 to 20 K with a temperature step of 20 K, and 6.7 ps of Verlet dynamics at each temperature step, using a time step of 3 fs. The force constant for distance restraints is ramped from 25 to 50 kcal mol<sup>–1</sup> Å<sup>–2</sup>, whereas that for backbone dihedral angles is ramped from 10 to 30 kcal mol<sup>–1</sup> rad<sup>–2</sup>. The structural restraints yielded an ensemble of 15 structures with rmsd of 0.92 Å for backbone and 1.37 Å for all heavy atoms (refinement statistics are given in Table 1). The structure of the V27A amantadine-resistant mutant has been deposited to the Protein Data Bank with PDB accession code 2KWX.

3. Results and discussion

3.1. Structure of the V27A drug resistant mutant

In order to directly compare the structure of the V27A mutant with that of the WT and the S31N mutant, we examined the V27A18–60 construct under the same conditions as those used in the NMR studies of WT18–60 [16] and S31N18–60 [19]. Under these conditions the V27A mutant yields NMR spectrum that is similar to those of WT and S31N, although demonstrates overall better spectral quality (Fig. 1A). Using a previously established liposomal protein flux assay [19], we showed that the V27A channel reconstituted in liposomes conduct protons ∼2 times faster than WT at pH ∼6 and that addition of 50 μM rimantadine only inhibited conductance by ∼1%, compared to near complete inhibition of WT18–60 by 50 μM rimantadine (Supplementary Fig. S1).

Fig. 1A shows significantly better resonance homogeneity (than that for WT [16]) that allowed the assignment of nuclear Overhauser enhancements (NOEs) between the TM helix residues 46 and residues 51 and 54 of the AP helices. These long-range NOEs were not observed in the previous structural study of WT18–60 due to resonance broadening. The near absence of distance restraints between the TM and AP helices resulted in a “detachment” of the AP helices from the channel domain in the WT (Fig. 2A and C). The NMR structure of V27A18–60 was determined by a total of 1008 NOE restraints (see Table 1 for structural statistics). Compared to WT, the structure ensemble of V27A shows a better-defined arrangement of the AP helices relative to the pore domain (Fig. 2B and D).

While the C-terminal region (residues 47–60) of the V27A structure is more compact due to the newly acquired NOE restraints, the channel pore is overall very similar to that of WT and the S31N mutant. As in the closed channel of WT18–60, the AP helix C-terminal end (around Gly58) of one subunit packs closely against the AP helix N-terminal end (around Ile51) of the adjacent subunit (Fig. 2D). The inter-subunit interaction between the AP helices, in addition to those between the TM helices, explains why the C-terminal sequence (47–60) beyond the TM domain is required for the stable assembly of the M2 tetramer [16,19,20]. Another interesting detail revealed by the V27A structure is the position of the Ser50 side chain. The native residue at position 50 is cysteine, which is palmitoylated in the virus [21]. This cysteine was mutated to serine in our structural investigation to avoid problems associated with potential disulfide bond formation. The V27A structure shows that side chains of Ser50 are pointing along the axial direction of the channel, which would allow, upon palmitoylation, the fatty acid chains to partition naturally into the lipid bilayer of the membrane.

3.2. Implications to the mechanism of resistance

Since there have been published results that are consistent with either of the two proposed sites of inhibition, the pore-blocking site [15,17,22] and the external site for allosteric inhibition [16,19,23], we discuss possible mechanism of drug resistance of the V27A mutant separately for the two different inhibition sites.

We previously proposed a mechanism of inhibition by rimantadine based on the external drug binding site for the S31N mutant [19]. This external, lipid-facing drug pocket is formed by Trp41, Ile42, and Arg45 from one TM helix and Leu40, Leu43, and Asp44

![Fig. 1. Spectra of the V27A18–60 mutant display residue specific assignment of backbone amide and side chain methyl groups. (A) 1H–15N tr-HSQC spectrum of 15N-, 13C-labeled protein. (B) 1H–13C HSQC spectrum of methyl groups of uniformly 15N-, 13C-labeled protein. Both spectra were recorded at 30 °C, pH 7.5, and 1H frequency of 600 MHz.](Image)
The weakening of the assembly can be explained by comparing the WT and V27A structures. In WT, the Val27 methyls provide a substantial amount of inter-helical van der Waals interactions that contribute to channel assembly. These interactions result in the formation of a tight hydrophobic ring that constrains the N-terminal channel opening. In the V27A structure, the side chains of Ala27 are too small to form strong inter-helical packing, which may be the cause of the weakened tetrameric assembly. Moreover, as in the case of S31N, we could not detect protein-rimantadine NOEs for the external drug pocket of the V27A mutant, suggesting that again a mutation in the N-terminal TM region can dramatically decrease drug binding to the external pocket through a long-range, allosteric effect.

Explaining the mechanism of drug resistance in the context of the pore-blocking model is more challenging due to the fact that at least three distinct pore-binding sites have been proposed (reviewed in [24]). Most recently, yet another new pore-blocking concept emerged: upon binding to the channel pore, a fraction of amantadine tumbles isotropically, i.e. does not have any preferable orientation, and does not appear to form any specific interaction with the pore-lining residues [17]. This concept infers that mutations that confer resistance should alter the properties of the pore. A comparison of the pores of the WT, V27A, and S31N structures (Fig. 3) show that the overall architectures of the pores are similar among the three variants except for local changes around the mutated residues. An obvious difference in the V27A structure is that the channel entrance is much wider than in WT. This altered feature should facilitate both entrance and exit of amantadine, and it is unclear how this effect could be linked to drug resistance. It is possible, however, that the adamantyl cage of amantadine interacts with the hydrophobic valine side chains and the drug’s amino group forms polar contacts with the Ser31 hydroxyl groups. Thus the V27A mutation would be expected to reduce the hydrophobic interactions with the drug. An alternative explanation is that the weaker, more dynamic tetrameric assembly of S31N and V27A weakens pore binding.

3.3. Implications to the proton transfer pathway

In addition to drug inhibition, a major area of interest in the M2 field is the mechanism of proton conduction. In the WT, the N-terminal channel opening is guarded by Val27 side chains, which hinder water entrance. Thus channel breathing may be required to admit water. The V27A structure shows that replacing Val27 with alanine more than doubles the channel opening (Fig. 3), thus it is expected that this mutation will increase proton flux rate by decreasing energy barrier for channel hydration. Inside the pore, water molecules are localized around Ser31 that may mediate proton passage to His37. What is unclear, however, is how protons exit the channel. The new V27A structure suggests that the protons may exit the channel near Asp44 or Arg45 (Fig. 4A and B). Asp44 and Arg45 are the only polar residues in the C-terminal region of the channel, and they are conveniently positioned at the lipid headgroups where they are accessible by water molecules. In particular, Asp44 is located at the lateral opening of the channel (Fig. 4A), thus it is capable of mediating the C-terminal water entrance. The C-terminal base of the channel is sealed by the hydrophobic side chains of Phes55 (Fig. 4C), making it impermeable to either water molecules or protons. Assuming that the base does not change conformation during proton conduction, the only possible proton exit is the lateral opening at Asp44.

In addition to water near Ser31, water crosspeaks are also present near the Trp41 indole amine in WT [16], S31N [19] and the V27A mutants. The water molecules around Ser31 may mediate proton transfer to His37, and the water molecules around Trp41 may mediate proton transfer from His37 to the channel exit at
Further experimental investigation is required to understand how protons pass the His37/Trp41 gate of the channel.

4. Conclusion

The solution NMR structure of the V27A amantadine-resistant mutant reveals a number of interesting features that have not been observed in any of the known experimental structures and models of the M2 protein. The structure shows a substantially increased channel opening at the N-terminal end, which may explain the faster proton conduction observed for the V27A mutant. The C-terminal region of the structure also strongly suggests that Asp44 and Arg45 facilitate lateral proton exit to the polar region of the membrane during proton conduction.
