SUMMARY

Many immune system receptors signal through cytoplasmic tyrosine-based motifs (ITAMs), but how receptor ligation results in ITAM phosphorylation remains unknown. Live-cell imaging studies showed a close interaction of the CD3ε cytoplasmic domain of the T cell receptor (TCR) with the plasma membrane through fluorescence resonance energy transfer between a C-terminal fluorescent protein and a membrane fluorophore. Electrostatic interactions between basic CD3ε residues and acidic phospholipids enriched in the inner leaflet of the plasma membrane were required for binding. The nuclear magnetic resonance structure of the lipid-bound state of this cytoplasmic domain revealed deep insertion of the two key tyrosines into the hydrophobic core of the lipid bilayer. Receptor ligation thus needs to result in unbinding of the CD3ε ITAM from the membrane to render these tyrosines accessible to Src kinases. Sequestration of key tyrosines into the lipid bilayer represents a previously unrecognized mechanism for control of receptor activation.

INTRODUCTION

T cell receptor (TCR) recognition of MHC-bound peptides is an essential step for the initiation of adaptive immune responses to invading pathogens and induces a complex signaling cascade that results in clonal expansion, cytokine production, and other effector functions (Davis and Chien, 2003). The TCR is one of the most complex multiprotein cell surface receptors and is composed of the ligand-sensing TCR heterodimer and three signaling subunits—CD3γε, CD3ζε, and ηε—that associate with the TCR in the membrane through a set of conserved ionizable transmembrane residues (Call et al., 2002; Davis and Chien, 2003). These signaling subunits contain cytoplasmic immunoreceptor tyrosine-based activation motifs (ITAMs) with a consensus sequence of YxxL/IxxL/I (Reth, 1989). The two tyrosines are phosphorylated by a Src kinase, Lck or Fyn, and a dually phosphorylated ITAM recruits the ZAP-70 protein tyrosine kinase, which in turn phosphorylates downstream components of the signaling pathway (Weiss and Littman, 1994). The phospho-tyrosine and leucine/isoleucine residues of each YxxL/I hemi-motif are bound by deep pockets of the tandem SH2 domains of ZAP-70 (Hatada et al., 1995). Binding of a dually phosphorylated ITAM peptide reorients the two SH2 domains relative to each other, destabilizing inhibitory interactions made by the linker connecting the SH2 and kinase domains. These conformational changes explain how ITAM binding induces activation of the ZAP-70 kinase domain (Deindl et al., 2007).

The central unresolved question in this field is how ligand engagement by the TCR ectodomains results in phosphorylation of the cytoplasmic domains of the three dimeric signaling subunits. This question is of general significance because many different receptors in cells of hematopoietic origin signal through cytoplasmic ITAMs, including the B cell receptor, several Fc receptors, a group of NK cell receptors, and many others (Reth, 1989; Weiss and Littman, 1994). A common feature among these receptors is that the ligand-binding subunit assembles with one or more dimeric signaling subunits with cytoplasmic ITAMs (Call and Wucherpfennig, 2007). ITAMs are, however, evolutionarily more ancient than the immune systems of mammals. The C. elegans engulfment receptor CED-1 and its Drosophila ortholog, Draper, are expressed by glial cells in the central nervous system and mediate phagocytosis of apoptotic neurons. Draper contains an ITAM motif (YxxLxxIxxL) that is phosphorylated by the Src kinase Src42A, resulting in recruitment of a tyrosine kinase (Shark) homologous to mammalian Syk and ZAP-70 (Ziegenfuss et al., 2008). Furthermore, ITAMs have been...
identified in membrane proteins of several viruses that can cause cellular transformation, including the envelope protein of mouse mammary tumor virus (MMTV), the LMP2A protein of Epstein-Barr virus (EBV), and the gp30 protein of bovine leukemia virus (Lu et al., 2006; Reth, 1989; Ross et al., 2006). MMTV uses the ITAM to activate Syk, and mutation of its ITAM substantially reduces the ability of this virus to induce transformation (Ross et al., 2006).

Most models of TCR triggering postulate a ligand-induced conformational change, but the structural consequences of such a conformational change remain unknown. Furthermore, textbooks depict the cytoplasmic ITAMs as flexible chains that float in the cytoplasm because peptides representing the cytoplasmic domains are unstructured in solution. However, a previous study showed that the cytoplasmic domain of the TCR z chain can bind to synthetic lipid vesicles that contain acidic phospholipids (Aivazian and Stern, 2000). Acidic phospholipids were tested because the lipid distribution of the plasma membrane is asymmetric and the most abundant negatively charged lipid, phosphatidylserine, is primarily localized to the cytoplasmic face through active transport mechanisms (Devaux, 1991). That paper reported that binding to synthetic acidic lipid vesicles substantially increased the a-helical content of the z cytoplasmic domain based on circular dichroism (CD) measurements, which suggested an a-helical conformation of the z chain ITAMs (Aivazian and Stern, 2000). However, a follow-up study by the same group concluded—again based on CD measurements—that the z cytoplasmic domain remained unstructured when bound to acidic lipid vesicles and that lipid binding only partially inhibited ITAM phosphorylation (Sigalov et al., 2006). The physiological relevance of lipid binding by ITAMs remained uncertain because membrane binding has never been demonstrated in cells, an issue that is critical because membrane binding by the z cytoplasmic domain primarily involved electrostatic interactions, which can be nonspecific.

In this study we have examined the functional relevance of membrane binding by ITAMs, using the CD3z cytoplasmic domain (CD3zCD) of the TCR as an example. Binding of CD3zCD to the inner leaflet of the plasma membrane was visualized in live cells by fluorescence resonance energy transfer (FRET) between a fluorescent protein attached to the C terminus of CD3zCD and a fluorescent membrane dye. The nuclear magnetic resonance (NMR) structure of CD3zCD in its lipid-bound state showed that two tyrosines of the ITAM are inserted into the hydrophobic core of the lipid bilayer. TCR triggering therefore has to result in dissociation of the ITAM from the membrane to render the tyrosines accessible to kinases.

**RESULTS**

**Identification of CD3zCD Sequence Elements Involved in Membrane Binding**

The CD3z cytoplasmic domain can be divided into three segments: a positively charged N-terminal segment with 10 basic residues, a proline-rich stretch, and the C-terminal ITAM (Figure 1). For quantitative comparison of a panel of CD3zCD mutants, we developed an equilibrium-based microdialysis assay (Figure 1A) in which movement of the large unilamellar lipid vesicles (LUVs) between the chambers was blocked by a dialysis membrane but Alexa 488-labeled CD3zCD could diffuse between the two chambers. When equilibrium had been reached the relative distribution of labeled peptide was determined in both the experimental chamber (LUVs containing acidic phospholipids) and the control chamber (LUVs composed of the zwitterionic lipid dimyristoyl-phosphatidylcholine, DMPC). The labeled CD3zCD peptide showed strong enrichment in the experimental chamber when it contained LUVs composed of acidic phospholipids, dimyristoyl-phosphatidylserine (DMPS), or dimyristoyl-phosphatidylglycerol (DMPG). Binding was also observed to LUVs formed with a mixture of lipids designed to approximate the composition of the inner leaflet of the plasma membrane (denoted as “Mix” in Figure 1B) (Fridriksson et al., 1999).

The 14 basic residues, of which ten are located in the N-terminal segment and four in the ITAM, were tested because the lipid distribution of the plasma membrane is asymmetric and the most abundant negatively charged lipid, phosphatidylserine, is primarily localized to the cytoplasmic face through active transport mechanisms (Devaux, 1991). That paper reported that binding to synthetic acidic lipid vesicles substantially increased the a-helical content of the z cytoplasmic domain based on circular dichroism (CD) measurements, which suggested an a-helical conformation of the z chain ITAMs (Aivazian and Stern, 2000). However, a follow-up study by the same group concluded—again based on CD measurements—that the z cytoplasmic domain remained unstructured when bound to acidic lipid vesicles and that lipid binding only partially inhibited ITAM phosphorylation (Sigalov et al., 2006). The physiological relevance of lipid binding by ITAMs remained uncertain because membrane binding has never been demonstrated in cells, an issue that is critical because membrane binding by the z cytoplasmic domain primarily involved electrostatic interactions, which can be nonspecific.

Membrane Binding by the CD3z: Cytoplasmic Domain in T Cells

Given the important contribution of electrostatic interactions it was critical to examine membrane binding in cells. Fluorescence resonance energy transfer (FRET) requires close spatial proximity between donor and acceptor fluorophores, typically a distance of <100 Å (Kenworthy, 2001). The CD3z cytoplasmic domain is 57 residues in length, and in a fully extended conformation its C terminus would be at a distance of ~200 Å from the membrane. Significant FRET between a fluorescent membrane dye and a fluorescent protein attached to the C terminus of the CD3z cytoplasmic domain should thus only be detected if the cytoplasmic domain indeed interacts with the lipid bilayer. We chose the monomeric teal fluorescent protein (mTFP1, abbreviated as TFP) as the FRET donor, one of the brightest and most photo-stable known fluorescent proteins (quantum yield of 0.85) (Ai et al., 2006). TFP has excitation and emission maxima at 462 nm and 492 nm, respectively, making it an ideal donor for yellow or orange acceptors (Ai et al., 2006). As the FRET acceptor, we selected octadecyl rhodamine B (R18), a plasma membrane dye with excitation and emission maxima at 540 nm and 565 nm (Figure S1 available online). Other studies have shown that fluorescent membrane dyes can be used to examine conformational changes of membrane proteins by FRET (Chigaev et al., 2003; Jiao et al., 2005).

We tested this strategy using constructs in which flexible linkers of increasing length (3, 25, and 50 residues) were placed between the transmembrane (TM) and TFP domains (Figure 2A). The construct with the 3 amino acid (aa) linker served as a positive control, and the 25 and 50 aa constructs were used to determine the FRET efficiency that might result when either the C-terminal ITAM or the entire cytoplasmic domain dissociate.
from the membrane, respectively. A residual FRET signal is expected even with a 50 aa linker because the TFP group can freely move within the space defined by the maximal length of the flexible linker. These cytoplasmic domains were attached to the TM domain of an irrelevant monomeric membrane protein, the inhibitory NK cell receptor KIR2DL3, with two extracellular immunoglobulin domains and no known interactions with the TCR. Jurkat cell transfectants that expressed these fluorescent proteins were cloned by single-cell sorting, and clones with similar expression levels were selected for analysis (Figure 2B).

FRET results in a reduction in the fluorescence intensity of the donor (TFP) due to energy transfer to the acceptor (R18), a process referred to as donor quenching (Kenworthy, 2001). Cells were captured onto glass coverslips and imaged using a flow chamber to enable real-time FRET measurements during R18 injection. R18 labeling of the plasma membrane resulted in substantial quenching of TFP fluorescence for the 3 aa linker positive control construct, indicative of a high FRET efficiency (>40%, Figures 2C and 2E; Movie S1). Minimal photobleaching of the donor (approximately 5%) was observed during these experiments due to repeated image acquisition during R18 labeling. This degree of photobleaching was observed for all constructs, and FRET values were therefore not corrected for this factor. Constructs with 25 and 50 residue linkers exhibited lower FRET
efficiencies (23% and 12%, respectively) that correlated inversely with the distance of the TFP domain from the plasma membrane (Movies S2 and S3). This reduction in donor fluorescence was only observed at the plasma membrane where TFP and R18 were colocalized, but not in intracellular compartments that only had a TFP signal (Figure 2E).

A second approach for FRET measurements is to photobleach the acceptor and measure the increase in donor fluorescence when its energy is no longer transferred to the acceptor (donor dequenching). Images of the donor fluorophore (TFP) were acquired prior to and after photobleaching of the acceptor (Figures 2D and 2F). Again, lengthening of the linker resulted in a stepwise reduction in FRET efficiencies. FRET efficiencies were moderately underestimated with this approach due to some bleaching of the donor (5–10%) during acceptor photobleaching.

We then placed the wild-type (WT) CD3<sub>3</sub>CD into this reporter construct (HA-KIR-CD3<sub>3</sub>CD-TFP) and measured, using both quenching and dequenching approaches, a high FRET efficiency similar in magnitude to the 3 aa linker control (Figures 3A–3D; Movie S4). To demonstrate specificity of binding, we analyzed a mutant in which six basic residues in the N-terminal segment of the CD3<sub>3</sub>cytoplasmic domain were mutated to serine (Emut1+2, Figure 1). Indeed, low FRET values similar to the 50 aa linker were obtained for this mutant (Figure 3; Movie S5). Also, the kinetics of R18 labeling and increases in FRET were closely correlated (Figure S2). Furthermore, the incorporation of photobleached R18 dye did not change the TFP fluorescence intensity, demonstrating that the change in TFP fluorescence caused by fluorescent R18 was due to FRET (Figures 3A and S2). These results firmly establish a close interaction of the CD3<sub>c</sub> cytoplasmic domain with the plasma membrane in T cells.

Figure 2. FRET Approach to Examine CD3<sub>3</sub>CD Membrane Binding in Cells

(A) Approach for measuring FRET efficiency as a function of the distance of TFP (FRET donor, labeled cyan) from a membrane labeled with R18 (FRET acceptor). Inset: Western blot analysis with HA tag mAb showing expression of all constructs in transfected Jurkat clones.

(B) FACS analysis of TFP fluorescence for clones expressing the different constructs. Numbers represent the mean fluorescence intensities for each clone.

(C and E) Measurement of FRET efficiency with the donor quenching approach. Cells were adhered to glass coverslips and loaded into a flow chamber, and Ringer solution (37°C) was injected over the cells (prequench: PQ). R18 was then injected and images taken at 20 s intervals for both channels. FRET efficiency was calculated based on the reduction of TFP fluorescence (quenched state: Q) due to energy transfer to the R18 acceptor (10 cells/construct, error bars indicate SEM).

(D and F) R18-labeled cells (quenched state: Q) were imaged in both channels and the acceptor was then photobleached (*) to release the quenched fluorescence (dequench: DQ). (D) FRET efficiencies were measured and plotted (14–17 cells shown here from one experiment).
Lipid Binding Induces Partial Folding of CD3

Based on far UV CD, CD3<sub>CD</sub> behaves as an unstructured protein in solution. However, the presence of acidic DMPG LUVs induced a shift in the CD spectrum consistent with partial folding (Figure 4A). Such a change was not observed with control DMPC LUVs, indicating a dependence on the interaction with the lipid. Interestingly, Emut4 and Emut5 lost their secondary structure even though these mutations within the ITAM did not substantially reduce lipid binding. These results indicate that both basic and hydrophobic residues of the ITAM contribute to the local structure of this segment (Figures 4B and 4C). The other mutants were not included in these experiments because of their poor binding to LUVs.

The structure of the lipid-bound state of CD3<sub>CD</sub> was then determined by multidimensional NMR spectroscopy. The critical aspect for determination of a physiologically relevant structure of the cytoplasmic domain was to provide a membrane surface suitable for solution NMR techniques. Detergent micelles do not adequately mimic the planar surface of the inner leaflet of the plasma membrane because they have a strong curvature. This is particularly true for polypeptides that reside on the surface of the membrane (Chou et al., 2002). Bicelles are disc-shaped structures composed of one or more long-chain phospholipids (such as 1-palmitoyl-2-oleoyl-phosphatidylglycerol, POPG) that assemble into a central bilayer and a short-chain lipid (such as dihexanoyl-phosphatidylcholine, DHPC) that forms the rim. The core region of bicelles thus mimics a section of natural membrane much better than micelles (Prosser et al., 2006).

The two-dimensional <sup>1</sup>H-<sup>15</sup>N heteronuclear single-quantum coherence (HSQC) spectrum of CD3<sub>CD</sub> in the absence of...
phospholipids showed moderately dispersed amide resonances, but inhomogeneous signal intensities indicated little or no structure (Figure S3A). For example, 4 out of 6 expected amide resonances from glycines were not observable due to fast exchange with solvent. In the presence of bicelles the spectrum showed greater peak homogeneity and all expected amide resonances were observed. This indicated that the protein was more structured and that the amide protons were protected by hydrogen bonds and the lipid bilayer environment (Figure 4D). Interestingly, arginine side chain NH, which exchange too quickly with solvent at pH 6.7 to be detectable in the HSQC experiment, appeared upon binding to bicelles. A control experiment using bicelles composed of the zwitterionic lipid POPC and DHPC yielded a spectrum virtually identical to free CD3\textsubscript{3CD} (Figure S3C), consistent with the biochemical data. As expected, the spectrum obtained in the presence of micelles formed by the detergent lysomyristoyl-phosphatidylglycerol (LMPG) was substantially different, confirming that micelles do not provide the same environment as bicelles even when both have the same acidic headgroup (PG) (Figures 4E and S3B).

Smaller bicelles tumble faster and yield more favorable relaxation properties for solution NMR studies, but they may not be large enough to accommodate a membrane-surface-binding protein such as CD3\textsubscript{3CD} with an elongated conformation. Larger bicelles resemble true membranes more closely but broaden the NMR resonances due to slower reorientation in solution. For structure determination, it was thus important to identify the optimal size of POPG/DHPC bicelles. Bicelle size is determined by the ratio of long-chain to short-chain lipids (the q value). We tested bicelles with q values of 0.5, 0.8, and 1.0. Chemical shift changes were observed between q = 0.5 and 0.8 but not between q = 0.8 and q = 1.0, indicating that the bilayer region at q = 0.8 was large enough to accommodate CD3\textsubscript{3CD}. A q = 0.8 bicelle is estimated to have a diameter of ~72 Å according to the corrected Vold-Prosser model (Glover et al., 2001).
The Key Hydrophobic Residues of the ITAM Are Deeply Embedded in the Membrane

All CD3-CD residues were assigned with standard sequential assignment techniques except for the two N-terminal residues, which are in fast exchange with water, and the proline residues lacking backbone amide protons (Figure 4F). To investigate the interaction of CD3-CD with the lipid, we measured nuclear overhauser effects (NOEs) between the lipid (POPG) and the peptide backbone as well as hydrophobic side chains. Bicelles were generated with deuterated DHPC and protonated POPG so that NOEs arose only from the interaction of the peptide with the POPG bilayer portion. Protons belonging to different chemical groups of POPG (the first headgroup glycerol, the second headgroup glycerol, and the acyl chains, Figure 5A) have distinct chemical shifts and could thus be used to position CD3-CD with respect to the lipid bilayer.

Figure 5. Aromatic and Aliphatic ITAM Side Chains of Bicelle-Bound CD3-CD Reside in the Hydrophobic Lipid Bilayer Interior

(A) Selected strips showing methyl NOEs from a 13C-separated, double-13C-filtered NOESY spectrum of 15N,-13C-labeled CD3-CD bound to POPG/DHPC bicelles (q = 0.8). Methyl-bearing side chains in the CD3-CD N-terminal (V12) and ITAM (I41, L48, L52) regions as well as the C terminus (V57) show strong NOEs to methylene protons from the lipid acyl chains and weak NOEs to lipid headgroup protons, but none to water, indicating a strong propensity to be located in the lipid bilayer hydrophobic core. Bicelles were prepared using protonated POPG and deuterated DHPC. Therefore, all NOEs to acyl methylene protons are to bilayer lipids rather than to bilayer-stabilizing short-chain lipids. *, incompletely suppressed protein methyl signals; †, water proton chemical shift.

(B) Strips from an aromatic 13C-separated, double-13C-filtered NOESY spectrum of the same sample as in (A) demonstrating NOEs from the side-chain ð and ÿ aromatic protons of Y38 and Y49 to methylene protons from the acyl chains in the interior of the lipid bilayer. The observation of NOEs to the tyrosine hydroxyl protons, which are normally in fast exchange with water, indicates that the hydroxyls are now protected by the lipid bilayer.

(C) Enlarged strips from (B). Although the ð and ÿ aromatic protons of Y38 and Y49 are overlapped, the two tyrosines could be distinguished by their backbone amide proton resonances.
We first measured NOEs between the peptide backbone amides and POPG protons in a three-dimensional (3D) 1H-separated NOESY experiment (200 ms mixing time). CD3\textsubscript{CID} and DHPC were deuterated to eliminate any amide-to-side chain and amide-to-short lipid signals (Figure S4). A number of hydrophobic residues only showed NOEs (distance of <5 Å) to lipid acyl chains and the POPG headgroup, but not to water, indicating that these backbone atoms are close to the membrane interior and the lipid headgroups. These include key residues of the ITAM, such as the first tyrosine and isoleucine residues of the ITAM (Y38 and I41). The second tyrosine of the ITAM may be less deeply embedded in the hydrophobic core of the lipid bilayer: Y49 HN showed a strong NOE to lipid methylenes but also weaker NOEs to the lipid headgroup and water, suggesting that this backbone atom may be positioned at the interface between the hydrated headgroup region and the hydrophobic interior.

We next conducted 3D 1\textsuperscript{3}C-separated and double-1\textsuperscript{3}C-filtered NOESY experiments (170 ms mixing time) to exclusively observe NOEs from the methyl and aromatic protons of the protein side chains to the protons of POPG (Figures 5A and 5B). Almost all methyl protons from Val, Ile, and Leu showed strong NOEs to lipid acyl chains but not to water. Leu48 and Leu52 also showed NOEs to the POPG headgroup, but the signals were much weaker than the NOEs to the lipid acyl chains. The aromatic protons of the two tyrosines showed substantial NOEs to lipid acyl chains. Although the aromatic protons H\textalpha{} and H\textbeta{} from the two tyrosines were overlapped in the aromatic NOESY spectrum, they were distinguishable based on their backbone amide proton chemical shifts (Figure 5C). It is intriguing that the Ile41 and Leu52 methyl protons also had NOEs to the Tyr38 and Tyr49 aromatic protons, respectively, indicating that the two hydrophobic residues of each ITAM hemi-motif (YxxI and YxxL) are within close proximity to each other. Therefore, the four functionally critical hydrophobic residues of the ITAM are deeply inserted in the hydrophobic interior of the lipid bilayer.

**NMR Structure of the Membrane-Bound State of CD3\textsubscript{CID}**

Due to the dynamic nature of CD3\textsubscript{CID} in the membrane, a structure ensemble calculated in the absence of a lipid bilayer is of questionable relevance. Therefore, the membrane-bound CD3\textsubscript{CID} structure was calculated and positioned in a lipid bilayer model by combining two major sets of restraints: protein NOE restraints measured by 1\textsuperscript{3}N- and 1\textsuperscript{3}C-separated NOESY experiments and protein-lipid restraints measured by the protein-lipid NOESY experiments. The conventional NMR structure calculation protocol does not support localization of a molecule relative to a lipid bilayer. We therefore introduced an atom-to-plane distance potential into the Xplor-NIH refinement program (Version 2.19, http://nmr.cit.nih.gov/xplor-nih/). By modeling the lipid bilayer as three parallel planes corresponding to the first POPG headgroup glycerol, the second POPG headgroup glycerol, and the hydrophobic acyl chains, we used the observed CD3\textsubscript{CID}-lipid NOEs to position CD3\textsubscript{CID} with respect to the lipid bilayer (see Experimental Procedures below for details). An ensemble
of 200 structures was calculated from 239 protein NOE-derived restraints and 142 plane restraints. Several dihedral angles predicted by TALOS were also used for the structure refinement (Table S1). Overall, the CD3εCD is deeply embedded into the polar headgroup and hydrophobic acyl chains region of the lipid, with many peptide backbone atoms being located close to the interface between the polar headgroup region and the nonpolar core of the lipid. This general position of the peptide enables interaction of the basic side chains with the charged headgroups of the lipid while simultaneously permitting deep insertion of hydrophobic residues into the hydrophobic interior of the bilayer. The ITAM segment (Asn35 to Asn53) whose hydrophobic residues (YxxI and YxxL) are inserted into the lipid bilayer is structured with helical turns surrounding the two tyrosines (Figures 6A and 6E). The aromatic rings of the two tyrosines are both inserted into the hydrophobic core of the lipid bilayer, which induces helical turn structures in the Pro36-Glu39 and Leu48-Leu52 stretches (Figures 6C–6E). Mutation of the four hydrophobic residues of the ITAM resulted in a loss of second-order structure based on CD measurements, indicating that lipid insertion of these side chains induces folding of the ITAM. In contrast, the long N-terminal segment shows substantial lateral flexibility (Figure S5), even though it is restrained with respect to the bilayer plane and positioned at the interface between the POPG headgroup region and the acyl chains (Figure 6B). The insertion of the key hydrophobic residues of the ITAM into the lipid bilayer thus renders the two tyrosines inaccessible to Src kinases in the lipid-bound state.

**Functional Relevance of Lipid Binding by the CD3ε ITAM**

The structural data indicate that the tyrosines should not be phosphorylated when the ITAM is lipid bound. An in vitro kinase assay showed that addition of POPG/DHPC bicelles, but not POPC/DHPC control bicelles, prevented phosphorylation of CD3εCD by Lck (Figure 7A). Also, no basal phosphorylation of endogenous CD3ε or the HA-KIR-CD3εCD-TFP reporter protein could be detected, but basal phosphorylation of the TCR ζ chain was observed, consistent with previous studies (Kersh et al., 1998). Based on the size difference between phosphorylated and nonphosphorylated ζ chains, it appears that only a small fraction is basally phosphorylated (Figure 7B).

**DISCUSSION**

The NMR structure of the CD3ε cytoplasmic domain in its lipid-bound state showed that the signature tyrosine and leucine/isoleucine residues of the ITAM are inserted into the hydrophobic interior of the lipid bilayer where they are inaccessible to Src kinases. Dissociation of the CD3ε ITAM from the membrane is thus required to render the tyrosines accessible to kinases. The FRET experiments unequivocally demonstrated that the ITAM is membrane bound in live, nonactivated T cells. Such a demonstration of membrane binding in live cells was critical for establishing the physiological significance of lipid binding because electrostatic interactions between acidic lipid headgroups and basic residues of CD3ε play a prominent role in membrane association. These findings may be relevant for many other receptors that signal through cytoplasmic ITAMs.

**Figure 7. Membrane Binding Renders the Tyrosines of CD3ε Inaccessible to Lck**

(A) Lipid binding prevents tyrosine phosphorylation of CD3εCD. The tyrosine residues of CD3εCD were efficiently phosphorylated by Lck in an in vitro kinase assay. Addition of POPG/DHPC bicelles but not control POPC/DHPC bicelles prevented tyrosine phosphorylation. Western blots were probed with a phospho-tyrosine antibody (biotinylated P-Tyr-100 and streptavidin-horseradish peroxidase, SA-HRP) and a CD3εCD antibody (CD3ε m20 and anti-goat IgG-HRP). (B) Neither endogenous CD3ε nor the HA-KIR-CD3εCD-TFP reporter protein are basally phosphorylated. HA-KIR-CD3εCD-TFP transfected Jurkat cells were solubilized using 1% NP40 and proteins were immunoprecipitated with CD3ε (6B10.2), CD3ε (UCHT1), HA (3F10), or FLAG (M2, isotype control) antibodies. Phosphorylated and total proteins were detected with a phospho-tyrosine antibody (biotinylated P-Tyr-100 and SA-HRP, upper panel), a CD3εCD antibody (CD3ε m20 and anti-goat IgG-HRP, which detects CD3ε and the reporter protein), or an antibody to the ζ chain (anti-CD3ε, 6B10.2-HRP, lower panel). SDS-PAGE was performed under nonreducing conditions.
An overall structural model of the ITAM-lipid interaction was developed using NOEs between the CD3ζ cytoplasmic domain and the lipid headgroup/acyl chain regions as structural restraints. Rather than binding to the surface of the membrane through interaction of basic residues with the headgroups of acidic phospholipids, the peptide backbone is embedded in the hydrophilic and hydrophobic layers of the membrane. This positioning enables deep insertion of the hydrophobic ITAM residues into the acyl chain region of the membrane. Studies on other membrane-interacting peptides, such as the MARCKS peptide and Ras family members (Heo et al., 2006; Yeung et al., 2006; Zhang et al., 2003), have shown that both hydrophobic and basic residues contribute to membrane binding, which is consistent with the lipid-CD3ζ ITAM interactions described here. The MARCKS peptide has five phenylalanine residues, and NMR measurements showed NOEs between the phenylalanine rings and the acyl chain protons of the lipid (Zhang et al., 2003). The membrane insertion model of the CD3ζ ITAM may thus be relevant to other membrane-interacting signaling domains.

Three functional segments of the CD3ζ cytoplasmic domain can be distinguished. The N-terminal half of the cytoplasmic domain contains a large number of basic residues that are critical for membrane binding, in particular the clusters of basic residues located in closest proximity to the TM domain. A polyproline stretch that has been shown to bind Nck is located between this N-terminal domain and the ITAM (Gil et al., 2002). Neither hydrophobic nor basic residues of the ITAM segment were found to make substantial contributions to membrane binding, but CD measurements indicated that they are nevertheless essential for the secondary structure of the ITAM in the lipid-bound state. It thus appears that the ITAM is less strongly bound to the plasma membrane than the N-terminal domain, suggesting that it is poised to dissociate from the membrane upon receptor ligation. The structural features of the ITAM support this conclusion: the ITAM is not folded into a complete α helix, which presumably would represent a more stable structure, but rather only contains helical turns centered on the critical membrane-embedded tyrosines. The Stern lab had first suggested that the ITAMs of the ζ chain fold into α helices upon lipid binding and later revised this model by proposing that the cytoplasmic domain is completely unstructured even in the lipid-bound state (Alivizatos and Stern, 2000; Sigalov et al., 2006). This study focused on a different cytoplasmic domain of the TCR-CD3 complex but indicates that aspects of both models are correct and likely to be of functional significance: the long N-terminal segment is highly flexible, while the close interaction of the hydrophobic residues of the ITAM with the lipid induces partial folding of the ITAM centered on the critical residues of the motif.

Functional studies support the conclusions based on the NMR structure. Phosphorylation of CD3ζ lipid binding and its behavior of the TCR in the lipid bilayer. Given the importance of the charge-charge interactions between the CD3ζ cytoplasmic domain and acidic phospholipids, transient changes in the local lipid environment could allow release of the CD3ζ ITAM from the membrane.

In summary, this study demonstrates that the ITAM of an activating receptor in the immune system is lipid bound in nonactivated cells. The sequestration of the key tyrosines into the hydrophobic core of the lipid bilayer visualized by the NMR structure represents a novel structural mechanism for regulation of receptor activation. Control over the phosphorylation state of this and other ITAMs is essential to regulate the inductive responses of immune effector functions that need to be engaged with great spatial and temporal resolution so that they are effective in protecting the host from invading pathogens without causing harm.

**EXPERIMENTAL PROCEDURES**

**Binding of CD3ζCD to Synthetic Lipid Vesicles**

CD3ζCD was expressed as a GST fusion protein in E. coli, separated from GST by enterokinase cleavage, purified by reverse-phase HPLC, and labeled at an N-terminal cysteine residue with an Alexa 488 maleimide derivative (Invitrogen, Carlsbad, CA, USA). LUVs composed of different phospholipids were generated as previously described (Wang et al., 2001), and binding of labeled CD3ζCD to LUVs was measured by microdialysis. At equilibrium (24 hr), the Alexa 488 fluorescence was measured in chambers containing LUVs composed of the zwitterionic lipid DMPC (control chamber) versus acidic phospholipids (experimental chamber).
NMR Structure of CD3_{Co} Bound to Bicelles

All NMR experiments were conducted on Bruker spectrometers at 27°C. Details of chemical resonance assignment and measurement of structural restraints are given in the Supplemental Data.

Structures were calculated using the program Xplor-NIH Version 2.19 (Schwieters et al., 2003) using high temperature simulated annealing (from 1000 to 200 K) of an extended CD3_{Co} polypeptide to satisfy protein NOEs and dihedral angles and protein-POPG NOEs. The protein NOE restraints were enforced by flat-well harmonic potential, with the force constant ramped from 5 to 30 kcal mol^{-1} Å^{-2}. In positioning the dynamic polypeptide in the lipid bilayer, three parallel planes given by y = -22 Å (the first POPG headgroup glycerol), -17 Å (the second POPG headgroup glycerol), and -11 Å (the hydrophobic acyl chain) were used to represent a leaflet of the POPG bilayer. Distance restraints between protein protons and lipid planes were enforced with flat-well harmonic potentials (±Δ), with the force constant ramped from 2 to 30 kcal mol^{-1} Å^{-2}. The value of Δ, or the size of the flat well in Å, was assigned based on the NOE intensity and the dynamic properties of phospholipid bilayer obtained from X-ray and neutron diffraction data (Wiener and White, 1992). In the current structure refinement, Δ = f(δ), where f is a scaling factor qualitatively assigned based on the relative NOE intensities, and (δ) is the width of the probability distribution of lipid component x = (δ|Plane) = 8, (δ|Plane2) = 3, (δ|Plane3) = 8. In addition to the distance restraints, a number of backbone dihedral restraints derived from chemical shifts (predicted by TALOS as “good”) were enforced by flat-well (±30') harmonic potentials, with force constant fixed at 30 kcal mol^{-1} rad^{-2}. An ensemble of 200 structures was calculated from 239 protein NOE-derived restraints, 7 protein backbone dihedral restraints, and 142 protein-lipid restraints. We selected 20 structures with the lowest number of violations to describe the conformational sampling of CD3_{Co} in the POPG lipid bilayer (Figure 6).

FRET Measurements

Constructs were transfected into human Jurkat cells by electroporation and stable clones were isolated by single-cell sorting. FRET between the C-terminal TFP domain and the membrane dye octadecylrhodamine B (R18, Invitrogen, Carlsbad, CA, USA) was measured by fluorescence microscopy (Zeiss LSM 510) using a flow chamber set-up to measure TFP quenching in real time. TFP fluorescence intensity in segments of the plasma membrane was measured before and during R18 injection, and the quenching FRET efficiency was calculated as E = (POQ/PQ) × 100, where PQ and Q are quenched and donor fluorescence. FRET measurements were also made using a donor dequenching approach in which TFP fluorescence was measured before and after photobleaching of the R18 acceptor. The dequenching FRET efficiency was calculated as E = (DQ/DG) × 100, where DQ and DG are dequenched and quenched donor fluorescence.

ACCESSION NUMBERS

The structure described in this paper has been deposited and assigned the RCSB ID code 1csb1006622 and the PDB ID code 2kf6.

SUPPLEMENTAL DATA

Supplemental Data include Supplemental Experimental Procedures, one table, five figures, and five movies and can be found with this article online at http://www.cell.com/supplemental/S0009-8674(08)01237-3.

ACKNOWLEDGMENTS

This work was supported by a grant from the NIH (AI054520 to K.W.W.), the Pew Scholars Program in Biomedical Sciences (to J.C.J.), a grant (to C.V.C.) and a fellowship (to C.X.) from the Arthritis Foundation, a Benacerraf Fellowship and a fellowship from the Canadian Institute for Health Research (to E.G.), a Helen Hay Whitney Foundation fellowship (to M.E.C.), as well as the Intramural Research Program of CIT, NIH (to C.D.S.).
